LECTURE 21

Random Forests

Using a bunch of overfitters to balance the Bias-Variance trade-off

Random Forests

Multiclass Classification

Decision Trees (conceptually)

- Creating Decision Trees in `sklearn`
- Evaluating Tree Accuracy
- Overfit Decision Tree Example

The Decision Tree Generation Algorithm

- Evaluating Split Quality
- Entropy
- Generating Trees Using Entropy

Avoiding Overfitting

- Restricting Decision Tree Complexity
- **Random Forests**

Summary and Context

CC BY NC SA

Random Forests: Harnessing Variance

As we've seen, fully-grown decision trees will almost always overfit data

- Low model bias, high model variance.
- In other words, small changes in dataset will result in very different decision tree.
- **Example**: Two models on the right trained on different subsets of the same data.

Random Forest Idea: Build many decision trees and have them vote.

CC BY NC SA

Random Forests: Harnessing Variance

What do we mean by vote?

- For a given x/y, use whichever prediction is most popular.

Consider example at right with 9 models.

- 6 votes orange, 3 votes green.
- Random forest prediction is orange.

This kind of methods is called **ensemble learning**.

CC BY NC SA

Building Many Trees

Big fundamental problem: We only have one training set.

How can we build many trees using one training set?

CC BY NC SA

How can we build many trees using one training set?

BY NC SA

Bagging

Bagging: Short for **B**ootstrap **AGG**regat**ING**.

- Generate bootstrap resamples of training data.
- Fit one model for each resample.
- Final model = average predictions of each small model.
- Invented by Leo Breiman in 1994 (Berkeley Statistics!).

CC BY NC SA

Measuring a Tree: Out-of-Bag (OOB) Prediction Error

- When we bootstrap a sample, we exclude some of the values.

- To test how well a tree generalizes, we want to test it's predictions on unseen values.

OOB: Predict the values that weren't in the bootstrap!

CC BY NC SA

Random Forests

- Bagging often isn't enough to reduce model variance!
  - Decision trees often look very similar to each other and make similar predictions.
  - Ensemble will still have low bias and high model variance.
  - E.g., one strong feature always used for first split.

CC BY NC SA

Random Forests

- Bagging often isn't enough to reduce model variance!
  - Decision trees often look very similar to each other and make similar predictions.
  - Ensemble will still have low bias and high model variance.
  - E.g., one strong feature always used for first split.

- **Idea:** Only use a random subset of ***m*** features at each split.
  - Usually $m = \sqrt{p}$ for decision trees used for classification.
  - Here p is the number of features.
- Algorithm creates individual trees, each overfit in a different way.
  - The hope is that the overall forest has low variance.

CC BY NC SA

Random Forests Algorithm

- *Bootstrap training* data T times. For each resample, fit a decision tree by doing the following:
  - Start with data in one node. Until all nodes **pure** or **unsplittable**:
    - Pick an impure node.
    - *Pick a random subset of m features.* Pick the ***best feature*** x and ***best split value*** β such that the **weighted entropy** of the resulting split is minimized
    - Split data into two nodes, one where $x \leq \beta$, and one where $x > \beta$
- To predict, ask the T decision trees for their predictions and take majority vote.

This approach has two hyperparameters T and m.

CC BY NC SA

Variable Importance

In a linear (logistic) model with standardized features, the coefficients tell us how important a feature is.

Random forests don't have coefficients, but gain the following idea:

- At each split, predictors are sampled at random.
  - The strongest predictor is chosen.
- Across many trees, we can record whether a feature was used.

Variable Importance: How often was a feature chosen as the strongest?

CC BY NC SA

Avoiding Overfitting with Heuristics

We've seen many approaches to avoid overfitting decision trees.

- Preventing growth.
- Pruning.
- Random forests.

These ideas are generally "heuristic"

- Not provably best or mathematically optimal.
- Instead, they are just ideas that somebody thought sounded good, implemented, then found to work in practice "acceptably" well.

CC BY NC SA

Fit "Acceptably" Well

The plot shows the results of NeurIPS 2003 challenge.

- x-axis shows 5 different data sets
- y-axis shows the test error for 5 different models
  - Each model represents *months* of work
- "Univariate Screened Features"
  - Lots of data pre-processing

The clear winner was Bayesian neural nets (black line).

- The random forests model, though...

CC BY NC SA

Hyperparameters

Only two! The number of trees and the number of predictors to try at each split!

BY NC SA

Hyperparameters

Only two! The number of trees and the number of predictors to try at each split!

...

BY NC SA

Hyperparameters

Only two! The number of trees and the number of predictors to try at each split!

...

Except we still have all of the Decision Tree parameters (including ones we haven't talked about):

- Number of trees (bootstrap resamples)
- Number of predictors, as well as
- Max depth of each tree
- Minimum samples to split
- Minimum impurity to split

In practice, we usually use CV for # trees and # predictors, and use the others at a default value.

Summary and Context

CC BY NC SA

Decision Tree Generation

Decision tree generation algorithm:

- All of the data starts in the root node
- Repeat until every node is either **pure** or **unsplittable**:
  - Pick the ***best feature*** x and ***best split value*** β such that the **weighted entropy** of the resulting split is minimized, e.g. x = `petal_width`, β = 0.8 has loss 0.66
  - Split data into two nodes, one where $x \leq \beta$, and one where $x > \beta$

Notes: A node that has only one type is called a "**pure**" node. A node that has duplicate data that cannot be split is called "**unsplittable**"

CC BY NC SA

Why Decision Trees?

Decision Trees present an alternative philosophy to logistic regression.

- Instead of a weighted sum of features, we use a series of yes/no questions.

Some advantages of a decision tree:

- Able to capture nonlinear relationships (at risk of overfitting).
- Output is more interpretable: You know exactly how the tree made a decision.
  - Example: Imagine trying to make an argument in a court case.
  - This is not true of random forests.

Some disadvantages:

- Care needs to be taken to avoid overfitting.
- Not as mathematically nice (e.g. Ridge Regression has a simple closed form solution).

If all you care about is accuracy (or precision) (or recall), use **cross validation** to pick between the two modeling philosophies.

CC BY NC SA

Random Forests Algorithm

- *Bootstrap training* data T times. For each resample, fit a decision tree by doing the following:
  - Start with data in one node. Until all nodes **pure** or **unsplittable**:
    - Pick an impure node.
    - *Pick a random subset of m features.* Pick the ***best feature*** x and ***best split value*** β such that the **weighted entropy** of the resulting split is minimized
    - Split data into two nodes, one where $x \leq \beta$, and one where $x > \beta$
- To predict, ask the T decision trees for their predictions and take majority vote.

This approach has two hyperparameters T and m (but there are others that we often ignore).

CC BY NC SA

Why Random Forests?

- Versatile: does both regression and classification.
- Invariant to feature scaling and translation.
- Automatic feature selection.
- Nonlinear decision boundaries without complicated feature engineering.
- Doesn't overfit as often as other nonlinear models (e.g. polynomial features).
- Example of **ensemble method**: combine the knowledge of many simple models to make a sophisticated model.
- Example of using **bootstrap** to reduce model variance.

CC BY NC SA

Participation Questions

BY NC SA

Q1

Which of the following does *not* change if the units of a feature are changed (e.g. using mm instead of inches):

A. The coefficients in a linear model

B. The coefficients in a logistic regression model

C. The optimal decision split point

D. The loss at the optimal split point

CC BY NC SA

Q2

Random forests are made from a bunch of decision trees, which tend to overfit. Therefore, we can expect random forests to overfit.

A. TRUE

B. FALSE

CC BY NC SA

Q3

Which of the following is not chosen via cross-validation?

A. The number of trees used

B. The number of parameters used

C. The optimal predictor at each split

CC BY NC SA

Q4

Which of the following concepts is *not* used in Random Forests?

A. Regularization

B. Cross-validation

C. Inference

D. Bootstrapping

E. The bias-variance trade-off

F. Minimizing a loss function

G. Prediction
